

Chapter 30

Thrombin-Like Enzymes in Snake Venoms

Stephen P. Mackessy

Abstract Snake venoms, particularly from vipers, are rich sources of serine proteinases, some of which contain thrombin-like activity. Following human envenomations, these toxins often produce rapid coagulopathies via the depletion of circulating fibrinogen, typically via specific proteolysis of the A α and B β subunits. Hypofibrinogenemia following bites may be prolonged, contributing to hemorrhagic effects of the venom and occasionally leading to life-threatening conditions such as disseminated intravascular coagulation. However, they have also been used as therapeutic drugs for treating a diversity of human disorders, including strokes, deep vein thromboses and cerebral and myocardial infarctions. Many snake venom thrombin-like enzymes (SV-TLEs) have been sequenced, and important structural elements (six disulfides, the catalytic triad) are highly conserved. SV-TLEs are commonly glycosylated, and this modification may confer a high level of stability; unlike trypsin, they are exceptionally stable in aqueous solution. Structurally, they are closely related to other serine proteinases such as trypsin and chymotrypsin, but as a result of gene duplication, accelerated point mutations and ASSET, venom TLEs have evolved a diversity of activities. The relationship between structure and function of the different venom serine proteinases is still unclear, and future studies of substrate specificity of this diverse family of toxins will help resolve this uncertainty.

Introduction

Thrombin is the key element of blood coagulation, and its activation is tightly regulated via a series of factor-dependent reactions of coagulation cascade. Disruption of thrombin's normal activity, via genetic defects, disease or severe injury, can result in serious health concerns, and so it is not surprising that there is an extensive literature

on this critically important serine proteinase. For example, a search of the PubMed citation database (<http://www.ncbi.nlm.nih.gov/sites/entrez>) in January 2010 using the term “thrombin” returned over 38,500 hits. It is therefore well beyond the scope of this chapter to discuss the many roles of thrombin in hemostasis, but numerous recent reviews are available (e.g., di Cera, 2008), and this chapter will focus on select aspects of thrombin-like enzymes from snake venoms.

A notable result of human envenomations by many species of snakes is the rapid onset of coagulopathies, including the loss of blood coagulability. Though most pronounced following viperid bites, profound (consumptive) coagulopathies are not infrequently observed following elapid bites, particularly by Australian species (Isbister et al., 2009; White, 2005, 2009). Many of the coagulopathies induced by snake venoms result from the activities of snake venom serine proteinases (SVSPs), and among these, the thrombin-like enzymes (TLEs) are among the best characterized and have been the subject of many studies and recent reviews (e.g., Phillips et al., 2009; Serrano and Maroun, 2005; Swenson and Markland, 2005). SVSPs are broadly distributed among venomous reptiles, and like several other toxin families, the diversity of pharmacologies associated with these enzymes has resulted from gene duplication and accelerated evolution (Deshimaru et al., 1996; Kordis and Gubensek, 2000; Nakashima et al., 1993, 1995; Ohno et al., 1998), insertion of new exons (Pawlak and Kini, 2008), extension of intron-exon boundary (Tamiya et al., 1999) and exchange of exon segments (Doley et al., 2008, 2009). Although studies on the additive/synergistic effects of venom components are uncommon, it is likely that TLEs potentiate the effects *in vivo* of other components, such as the hemorrhagic metalloproteinases. Serine proteinases are most abundant among viperid venoms (e.g., Braud et al., 2000), and members of this protein family may comprise 20% or more of the venom proteome (e.g., Alape-Girón et al., 2008; Calvete et al., 2009; Sanz et al., 2006). Serine proteases which affect other components of hemostasis also have been characterized from a colubrid snake venom (Assakura et al., 1994) and from lizard venoms and saliva (Fry et al., 2006; Utaisincharoen et al., 1993), but at present, none appear to induce life-threatening coagulopathies. However, one colubrid, *Dispholidus typus* (Boomslang), does produce a potent procoagulant glycoprotein of ~55–67 kDa (Hiestand and Hiestand, 1979), but it remains incompletely characterized and may not be a serine protease.

Clotting disorders can occur at many levels in the blood clot cascade, but among venomous reptiles, targeting of fibrinogen patency is most common. Thrombin-like enzymes in venoms are serine proteinases and are typically responsible for the specific cleavage of fibrinogen A α or/and B β chains, and their actions *in vivo* lead to rapid defibrinogenation (Phillips et al., 2009; Serrano and Maroun, 2005; Swenson and Markland, 2005). Metalloproteinases, abundant in reptile venoms (Fox and Serrano, 2008, 2009), also typically hydrolyze fibrinogen *in vitro* (e.g., Mukherjee, 2008; Weldon and Mackessy, 2010), and some may also catalyze hydrolysis of the γ chain of fibrinogen and fibrin clots (Mackessy, 1993a, 1996). Many metalloproteinases can be considered to be less specific in their actions toward fibrinogen, as suggested by time course digests which result in production of numerous degradation fragments (Mackessy, 1993a) and their activities toward other structural

Table 30.1 Some properties of thrombin-like snake venom proteinases

| Species | Name | Activity | UniProtKB accession # | Mass | Inhibitors | References |

Table largely from Serrano and Maroum (2005) and Phillips et al. (2009)

proteins (Escalante et al., 2006)), and their pro- or anticoagulant activities will not be considered further here. However, it is likely that functionally important interactions occur among these venom components, and hypofibrinogenemia (TLE-catalyzed) accompanied by structural degradation catalyzed by metalloproteinases may produce uncontrollable hemorrhage. For the snake, these actions are important for prey incapacitation and facilitation of digestion; in human envenomations by vipers, these proteinases produce some of the more debilitating and difficult to manage effects (Gutiérrez et al., 2009).

Defining which of the myriad serine proteases often found in a single venom is a TLE-SVSP can be challenging, as many have similar activities toward model substrates such as paranitroaniline-derived peptides as well as toward native protein substrates such as fibrinogen. Further, the term “thrombin-like” is also problematic, because unlike most TLEs, thrombin is a multifunctional enzyme with rather different roles depending on physiological environment (Kini, 2005; Phillips et al., 2009). Additionally, most TLEs have not been assayed with a wide series of substrates (some are defined by sequence homology only), so the true specificity of activity, or lack thereof, is not well defined. Some of the SVSPs labeled as thrombin-like enzymes in the databases are incorrectly assigned to this activity, and some (particularly sequences derived from cDNA libraries) are labeled as TLEs because of sequence homologies but without any activity data. A more limiting definition of venom TLEs is needed, but for the present review, SVSPs which have specific catalytic activity toward fibrinogen A α or/and B β chains will be considered as TLEs. A list of many well-defined venom TLEs is provided in Table 30.1, along with major activities and biochemical attributes.

Structural Features of Snake Venom TLEs

Primary and Secondary Structure

Snake venom thrombin-like enzymes are serine endopeptidases which are members of the trypsin-like serine protease superfamily, the S1 family of peptidases, clan PA and subclan S (Marchler-Bauer et al., 2009; Rawlings et al., 2004a, b). Well over 100 sequences of SVSPs are available in databases such as NCBI (<http://www.ncbi.nlm.nih.gov/>) and UniProtKB (<http://www.uniprot.org/>), with 77 entered as thrombin-like enzymes in UniProt (December 2009). These enzymes have a high level of sequence identity (>60%; Kini, 2005) and are structurally constrained by the presence of six highly conserved disulfide bridges (Fig. 30.1), five of which are common to all S1 serine proteinases. The catalytic triad typical of the chymotrypsin/trypsin superfamily (His57, Asp102, Ser195; chymotrypsinogen numbering) is also highly conserved, as are numerous flanking residues, and SVSPs are typically classified as serine proteinases by the common sensitivity to the serine active site inhibitors PMSF and DFP (Serrano and Maroun, 2005).

Fig. 30.1 Sequences of snake venom thrombin-like enzymes, TLEs and several additional SVSPs which show greater than 50% sequence identity with batroxobin are shown. Sequences are listed by UniProt Accession numbers, and names and species identities are provided in Appendix. *Shaded residues:* H, D and S – conserved histidine 57, aspartic acid 102 and serine 195 residues of the catalytic triad; residues 35–41, 59–66, 92–99 – segments i, ii and iii undergoing ASSET and likely important surface residues involved in substrate recognition/binding (Doley et al., 2009); C – represent highly conserved cysteine disulfide pairs (residues 22–157, 42–58, 91–245, 136–201, 168–182, 191–220). Numbering above sequences is based on chymotrypsin

Fig. 30.1 (continued)

Biological solutions to structural needs are often frugal, and biological designs are typically conservative; this truism is notably observed among the SVSPs, which, in spite of a highly conserved primary structure and molecular fold, have evolved into a diversity of different pharmacologies (Serrano and Maroun, 2005), most of which cause dysregulation of the highly ordered coagulation cascade of vertebrates. Thrombin-like SVSPs typically target fibrinogen, but even within this target, TLEs from different sources may catalyze preferential hydrolysis of the A α and/or B β chains. SVSPs are typically very stable molecules, in large part due to the six disulfides found in most. Purified thrombin-like and kallikrein-like SPs from *Crotalus* and *Sistrurus* venoms are unaffected by the relatively harsh conditions of RP-HPLC, and they retain most activity even after long storage (>1 year) in solution at 4°C (Mackessy, unpublished observations). As noted below, part of this exceptional stability may be due to the carbohydrate moiety typical of most SVSPs.

Glycosylation

Venom serine proteinases are commonly glycosylated, and the carbohydrate moiety is commonly Asn-linked (Tanaka et al., 1992). The extent of *N*- or *O*-glycosylation appears to be significant but quite variable, and the functional significance of this variation is incompletely understood (Serrano and Maroun, 2005). Carbohydrate content may account for 5–30% of the total mass, and in a few cases the mass of the carbohydrate moiety (62%) may exceed that of the protein component (Paes Leme et al., 2008). However, the presence of these carbohydrate moieties can have important functional consequences. Glycosylation appears to confer greater thermal stability to BJ-48, a TLE isolated from *B. jararacussu* venom, and deglycosylation also greatly increases susceptibility to trypsin inhibitors such as STI (Silva-Junior et al., 2007). Glycosylation also conferred to *Bothrops* protease A (*B. jararaca* venom) thermal protection and protection against protein inhibitors (soybean trypsin inhibitor {STI}, bovine pancreatic trypsin inhibitor {BPTI}, antithrombin III) but did not protect against inhibition by benzamidine, further indicating a steric protective effect against the larger molecules (Botos and Wlodawer, 2007; Paes Leme et al., 2008). The smaller inhibitor molecule appears to enter/bypass the “protective cage” of the carbohydrate moiety essentially unimpeded. Interestingly, a similar protective mechanism has been demonstrated for glycosylation of the nicotinic acetylcholine receptor of *Naja haje* snake muscle: the small neurotransmitter (acetylcholine) does not experience steric hindrance by the carbohydrate “cage”, but the much larger α -neurotoxins are excluded from nAChR α -subunit binding sites, conferring resistance to the snake (Takacs et al., 2001). When glycosylation is eliminated, the receptor showed sensitivity to the neurotoxin similar to that of mammalian preparations. Partial deglycosylation of BPA did not increase susceptibility of the enzyme to protein inhibitors, nor did it significantly increase inhibition by benzamidine, but activity toward both fibrinogen and D-Val-Leu-Arg-pNA was enhanced (Paes Leme et al., 2008). These results indicate a type of

functional trade-off between optimal enzyme activity and in vivo stability, suggesting that the protective effect of glycosylation is not without some cost to enzyme efficacy.

Two SVSPs with apparent thrombin-like activity were isolated from *Deinagkistrodon acutus* venom and shown to be *N*-glycosylated at Asn35, as observed from electron density maps of this region of the crystal structures (Zhu et al., 2005). Because this glycosylation site occurs close to the active site, it was interpreted to restrict access of larger molecules like STI and BPTI. Structural analyses using superimposition of the venom SVSPs and trypsin-STI complex demonstrated collision between side-chain residues of STI and the carbohydrate moieties of the SVSPs. Again, it appears that glycosylation of these serine proteases creates steric hindrance of inhibitor binding, thereby protecting the enzyme. Most TLEs also are glycosylated, and it is likely that glycosylation has been selected for as a protective mechanism against endogenous serine protease inhibitors of snake prey species. The effect of glycosylation may therefore be to increase effective half-life in prey tissues and to increase probability of fibrinogen depletion. In human envenomations by rattlesnakes (*Crotalus*), recurrent coagulopathies are commonly encountered following antivenom treatment (Boyer et al., 1999), and it would be of interest to determine if glycosylated TLEs are involved in these persistent and recurrent cases of hypofibrinogenemia and thrombocytopenia.

Crystal Structures and Structural Predictions

At present, no crystal structures of snake venom TLEs have been solved. The structure of a plasminogen activator from *Trimeresurus stejnegeri* venom was resolved at 2.5 Å (Parry et al., 1998), and this protein has a high degree of sequence identity with snake venom TLEs. Several glycosylated serine proteases from *Deinagkistrodon acutus* venom have also been crystallized and their structures solved at 2.1 Å (Zhu et al., 2005); because they have fibrinogenolytic activity, they were considered to be TLEs (Philipps et al., 2009), but activity toward pNA-derived peptide substrates showed that they lacked the specificity often observed for other TLEs, for example from *Crotalus* venoms (e.g., Mackessy, 1993b). A preliminary crystallographic analysis of RVV-V from *Daboia russelli* venom was just published (Nakayama et al., 2009), and the structure should be available soon. Although this enzyme has been considered a TLE, it appears to be a specific activator of Factor V only, although it also showed amidase activity toward the TLE substrate Phe-pipecolyl-Arg-pNA. A theoretical model of this protein has been constructed (Segers et al., 2006), based on the several related SVSP structures which are currently available.

Because of conserved primary structure and disulfide pattern of SVSPs generally, it is probable that venom TLEs have a structure similar to that of other S1

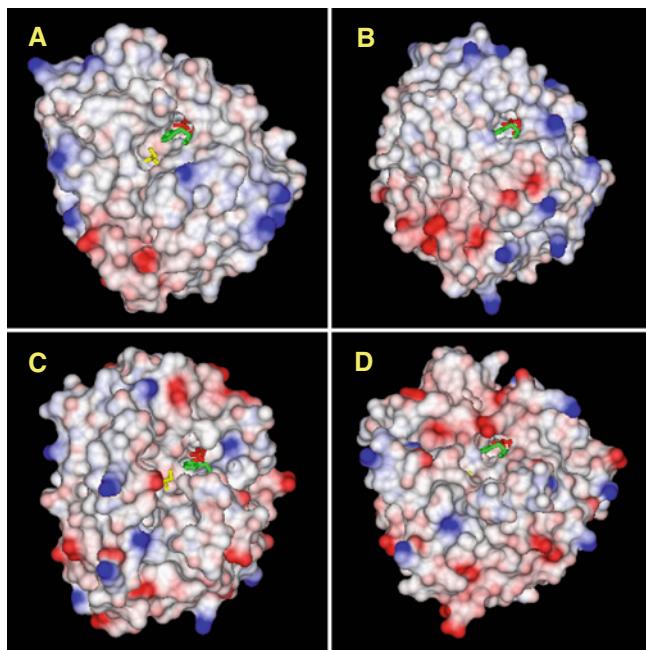

Fig. 30.2 Space-filling models of serine proteases. (a) Bovine trypsin (PDB ID: 1AQ7); (b) Bovine chymotrypsin B (PDB ID: 1DLK); (c) Venom serine proteinase Dav-PA (*Deinagkistrodon acutus* venom; PDB ID: 1OP0). (d) Venom plasminogen activator TSV-PA (*Viridovipera (Trimeresurus) stejnegeri*) venom (PDB ID: 1BQY). Models were drawn with Discovery Studio ViewerPro showing van der Waals radii and partial charges (red, negative; blue, positive). Active site residues His57 (green), Asp102 (red) and Ser195 (yellow) are shown in stick models. In B and D, Ser195 is barely visible. Note that although overall topology is similar, surface charge density and apparent accessibility to the active site vary between the molecules

serine proteinases, as molecular modeling of LM-TL (a TLE from *Lachesis muta* venom) has indicated (Castro et al., 2001). The overall similarity in molecular fold and active site orientation can be seen from comparisons of structural models of bovine chymotrypsin (MacSweeney et al., 2000) and trypsin and the SVSPs Dav-PA and TSV-PA (Fig. 30.2). Differences in surface charge densities are likely important for conferring observed differences in substrate specificity.

Gene Structures

At present, the gene structure for batroxobin (from *Bothrops moojeni* venom) remains the only published genomic representative of a snake venom TLE (Itoh et al., 1988). The gene is approximately 8 kbp, and the generally shorter exons (exon 1 = 240 bp; exon 2 = 151 bp; exon 3 = 260 bp; exon 4 = 134 bp; exon 5 = 728 bp) are interrupted by introns varying in length from 2.5 kbp (intron 1) to 0.35 kbp

(intron 4). In this respect, batroxobin is similar to trypsin, which also has 5 exons and 4 introns (Craik et al., 1984); both differ in organization from chymotrypsin, which has 7 exons and 6 introns (Bell et al., 1984).

Relations to the Charge Relay Catalytic System of Model Serine Proteases: Chymotrypsin/Trypsin

Thrombin-like serine proteases from snake venoms possess the highly conserved functional residues of the catalytic triad (Ser195, His57, Asp102) characteristic of the well-known serine proteases (e.g., Polgár, 1971) such as chymotrypsin (EC 3.4.21.1). They are members of the S1 serine proteinase family, PA clan of endopeptidases and they share the same basic fold in the catalytic domain with other members of the family, such as trypsin, chymotrypsin and thrombin. Peptide bond hydrolysis occurs via a two step acylation–deacylation reaction, with serine acting as a nucleophile and histidine as a proton donor/acceptor within the catalytic cleft; a hydrogen on the histidine imidazole ring is transferred to the aspartate carboxylate, forming a charge relay system. The mechanism of catalysis has been known for a long time (Hartley and Kilby, 1954; Polgár, 1971; Polgár and Bender, 1969) and has become a classic example in biochemistry courses of enzyme-catalyzed hydrolysis. The importance of the serine residue to snake venom TLEs, as well as unequivocal demonstration of a SVSP, is now routinely confirmed via specific active site inhibitors such as DFP, PMSF and AEBSF, which irreversibly and covalently modify serine in the catalytic cleft.

Distribution and Evolution of Snake Venom TLEs

Occurrence and Relative Abundance in Snake Venoms

Thrombin-like enzymes are found most frequently and as major components in the venoms of viperid snakes (Mackessy, 2009). Uncommonly, TLEs are present in elapid venoms (e.g., Jin et al., 2007), but they appear not to be broadly distributed among species of this family. Although there are reports of serine proteases in venoms from “colubrid” rear-fanged snakes (Assakura et al., 1994; Mackessy, 2002) and several lizards (Fry et al., 2006), TLEs do not appear to occur in venoms and salivas from these species. Serine proteases make up ~2.6% of the venom proteome of *Philodryas olfersii* (Ching et al., 2006), a colubrid snake capable of producing serious human envenomations, but this venom also does not appear to contain TLEs. Venom from *Alsophis portoricensis* (Puerto Rican Racer, family Dipsadidae) was recently shown to contain low activity toward the thrombin substrate Bz-PheValArgpNA (Weldon and Mackessy, 2010), but the levels are an order of magnitude lower than seen in most rattlesnake venoms.

Mechanisms of Evolution of SV-TLEs

Gene Duplication

A common means by which diversity is generated in a specific protein family is via gene duplication. In a critically important component of a complex system, such as thrombin in the blood clot cascade, mutation of specific residues which change activity levels or specificity of substrate recognition could be lethal mutations. However, when the gene is duplicated and one member remains static, the functional product of the original gene remains intact. The other gene copy is freed from selective constraints favoring conservation of original structure/function, and mutations can then lead to production of a novel activity. Repeated gene duplication can result in multiple copies of closely related genes being present, and over evolutionary time, a diverse set of pharmacologies within a structurally conserved protein family may result (Ogawa et al., 1996; Nobuhisa et al., 1996; Kini and Chan, 1999). This appears to be of common occurrence among snake venoms, and venom gene duplication has resulted in a multigene family of SVSPs (Deshimaru et al., 1996), giving rise to venoms with numerous serine proteinases. For example, in the venom of the Desert Massasauga (*Sistrurus catenatus edwardsii*), 24% of the proteome (Sanz et al., 2006) and >37% of the transcriptome consists of serine proteinases (Pahari et al., 2007). The transcriptome analysis showed 12 distinct isoforms of SVSPs, and fractionation of the venom has revealed at least 8 distinct serine proteinases are translated (Mackessy, unpublished observations). At least three of these SVSPs show thrombin-like activity, as assessed by preferential hydrolysis of the substrate Bz-Phe-Val-Arg-pNA over other Arg-terminal substrates (Mackessy, 1993b).

Accelerated Point Mutation

Single nucleotide replacement within an exon can have ramifications on function ranging from neutral to lethal mutation. One of the best documented single point mutations resulting in extreme alteration of function involves the sickle mutant of human hemoglobin which has resulted from the selective pressures of malarial parasites on humans (Huisman, 1993). Among snake venom toxins, point mutations have also occurred commonly and contribute to the primary structure diversity seen among homologous toxins from different species. Many of these point mutations appear to be functionally inconsequential; for example, small variations in sequence of α -neurotoxins from closely related species still results in a three-finger toxin with very high affinity for nicotinic acetylcholine receptors of skeletal muscle (Nirthanan and Gwee, 2004). However, among many toxin families, including SVSPs (Deshimaru et al., 1996), point mutations within protein-coding regions have occurred at a rate greatly accelerated relative to other proteins and even to the highly conserved UTRs within the same protein. Analysis of substitution rates between untranslated and translated regions demonstrated that nucleotide substitutions occurred much more frequently in protein-coding regions, and this unusually

high rate of substitution has contributed in part to the diversification of functionality. The ratios of non-synonymous to synonymous substitutions within coding regions were generally greater than 1 (0.67–1.64), whereas these ratios in typical isozyme genes were typically less than 0.2 (Deshimaru et al., 1996), again highlighting the rapid evolution of these toxin genes relative to non-toxins. This accelerated evolution within the SVSP multiple gene family is likely driven by selective pressures favoring multiple toxin activities against snake prey and predators.

ASSET

Recently we have shown that in addition to accelerated point mutations, many snake venom toxins also evolve via accelerated segment switch in exons to alter targeting (ASSET; Doley et al., 2009). The occurrence of ASSET is particularly interesting, as it seems to occur primarily in specific surface segments, while accelerated

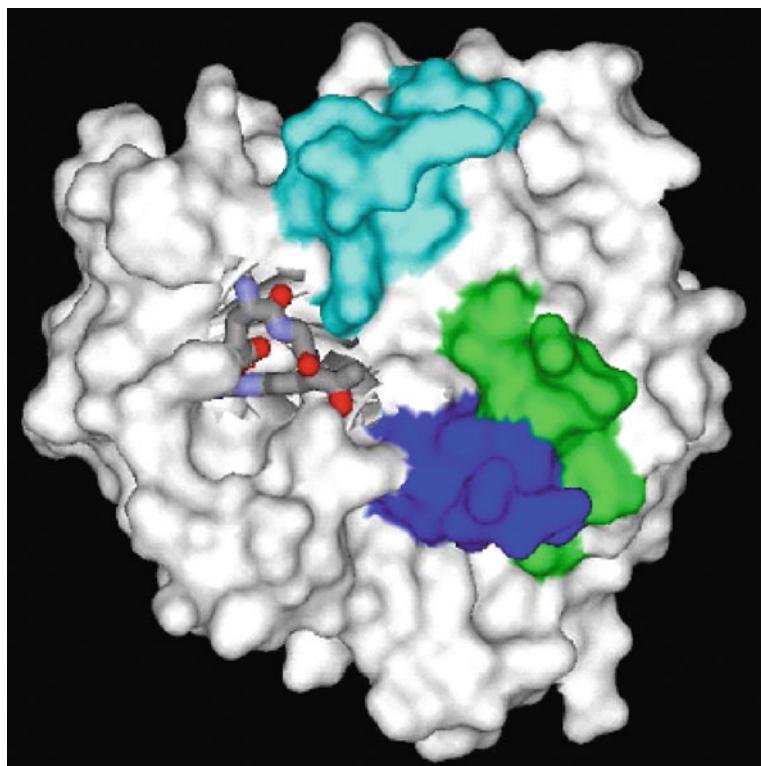

Fig. 30.3 Surface model of venom plasminogen activator (TSV-PA) from *Viridovipera* (*Trimeresurus*) *stejnegeri* venom (PDB ID: 1BQY). The segments that undergo exchange are shown in green, dark blue and turquoise color; note that the substrate binding area is the region shown in turquoise. The side chains of the active site residues are shown as ball and stick. From Doley et al. (2009)

point mutations occur in the rest of the molecule; among SVSPs, this includes those regions associated with substrate binding. ASSET therefore could produce rapid functional differentiation of gene products which share a highly conserved molecular fold and apparent surface topology (see Fig. 30.2). In viperid venoms in particular, numerous SVSP cDNAs have been sequenced, including many from *Viridovipera stejnegeri* (Tsai and Wang, 2001), *Deinagkistrodon acutus* (Zhang et al., 2006) and *Sistrurus catenatus edwardsii* (Pahari et al., 2007), demonstrating the high level of multiplicity of SVSPs in the venom and gland transcriptome of even a single individual. At least part of this diversification has occurred via ASSET.

ASSET has been hypothesized to be a mechanism of accelerated evolution of venom toxins which can confer new pharmacological functionalities on a conserved molecular fold, as is common among venom proteins. By switching functionally important segments of gene (protein) sequence, such as that important to substrate binding, rapid large scale changes in substrate specificity can occur. Such a mechanism appears to be important in the evolution of SVSPs (Doley et al., 2009), as the regions of exchange include those known to involve substrate binding (Fig. 30.3). ASSET can result in large-scale functional changes, with accelerated point mutations “fine-tuning” substrate fit. This hypothetical scenario may explain the variety of substrate specificities (thrombin-like, kallikrein-like, plasmin-like, arginine esterase, etc) seen among the SVSPs.

Structural and Phylogenetic Relationships

As mentioned above, SVSPs including TLEs show a high level of sequence identity, and the genes are obviously closely related. One might predict that functional classes of the SVSPs (thrombin-like, kallikrein-like, plasmin-like, etc) should cluster following structural cladistic analyses, and this prediction has been borne out by some studies (i.e., Wang et al., 2001). In this study, three functional subtypes clustered into discrete groups (thrombin-like {coagulating}, kallikrein-like {kininogenase} and plasminogen activators). However, a different analysis (Lee and Park, 2000) resulted in the clustering of functionally different SVSPs. A more recent analysis of sequence relationships among TLEs indicated a common ancestry among the SVSPs analyzed but did not demonstrate unequivocal clustering of functional subtypes (Castro et al., 2004). Because of these discrepancies, a phylogenetic analysis of TLEs and other SVSPs was undertaken using ClustalX and bootstrapped neighbor-joining method. One hundred and fifty-one snake venom serine protease sequences were retrieved from the UniProtKB database (<http://www.uniprot.org/>; January 2010) using the primary sequence of batroxobin in a BLAST search and the criterion of having >50% sequence identity with this target. Five SP sequences from lizards (sequence identity ~40%) were also included. Bovine and human trypsin sequences were used as outgroups, and bovine chymotrypsinogen and human thrombin were included in alignments and subsequent analyses (160 sequences

total). Sequences were aligned using ClustalX 1.81 (Thompson et al., 1994) and sequence similarities were evaluated using the bootstrapped neighbor-joining algorithm (1,000 bootstrap trials). The resulting NJ tree was drawn using FigTree 1.2.1 (available at <http://tree.bio.ed.ac.uk/software/figtree/>) and nodes were coded as to

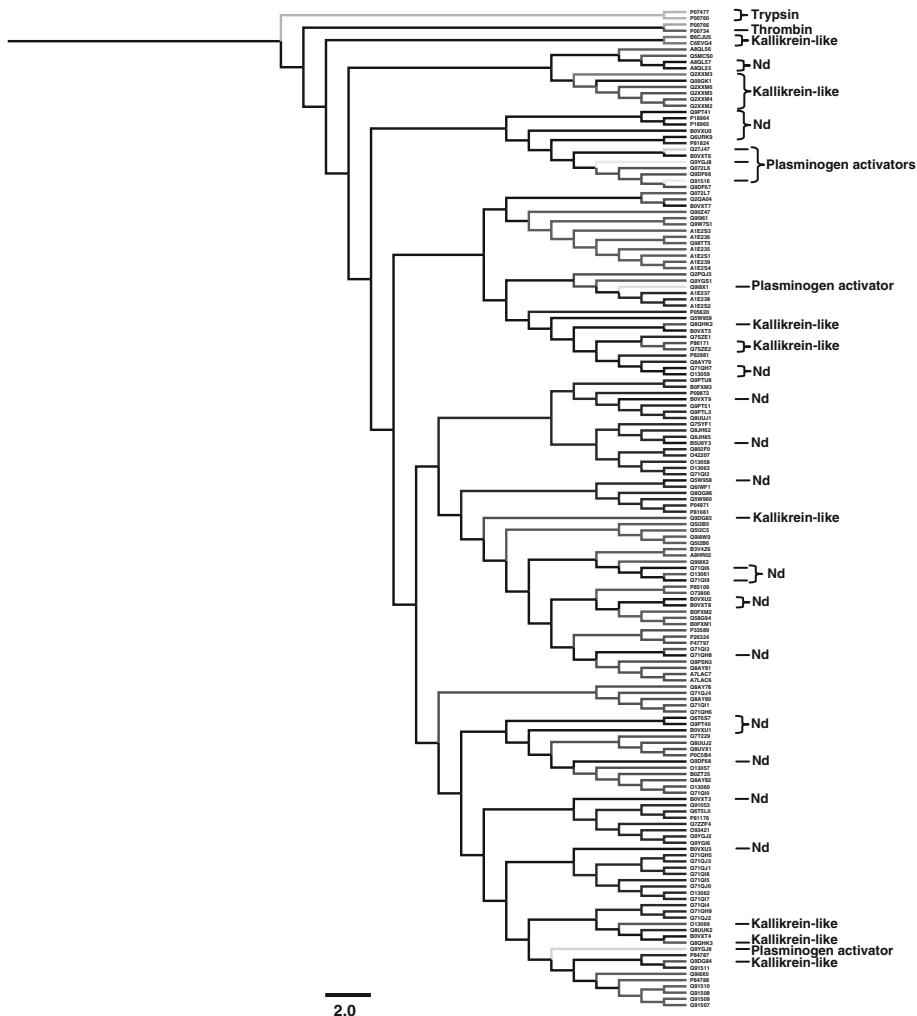

Fig. 30.4 Bootstrapped neighbor-joining tree of relationships among TLE and SVSP. The sequences are shown in Fig. 30.1. Although there is a trend toward clustering of similar activities (such as kallikrein-like activities), kallikrein-like and plasminogen-activating activities are distributed throughout many clades dominated by TLEs, suggesting that similar primary sequence motifs alone are not responsible for differences between activities. Kallikrein and plasminogen activating SVSPs are labeled; unlabeled nodes are all thrombin-like enzymes. Nd, activity not determined

functionality based on database-reported activity. The majority of sequences were identified as thrombin-like enzymes in the UniProt database, with a smaller number of kallikrein-like (14) and plasminogen activator (5) sequences identified; 28 were of unknown/undefined activity. Although there is a tendency for similar function sequences to cluster (Fig. 30.4), there are instances of all three activities occurring within many clades, suggesting that functionality is not dependent on sequence features alone. Effects of phylogenetic constraint (closer evolutionary relatedness of species) were not specifically analyzed but seem unlikely to play a major role. A more likely limitation of this analysis is that the absolute function of many SVSPs is equivocal or unknown. As others have noted, the relationship between sequence homology and biological activity remains paradoxical (Serrano and Maroun, 2005).

Biomedical Applications of SV-TLEs

Therapeutic Use and Drug Discovery

Snake venoms consist of a myriad of potent biological activities which have been recruited from various tissues and which mimic many natural regulatory components (Fry, 2005; Stocker and Meier, 1989). Because venom protein components profoundly affect homeostasis at numerous levels, there is a long-standing interest in venoms as a source of drug discovery and development (for a review, see Fox and Serrano, 2007). One of the earliest drugs related to hemostasis developed from a venom and approved for human use is Captopril, an inhibitor of angiotensin-converting enzyme which was based on bradykinin-potentiating peptides isolated from *Bothrops jararaca* venom (Ferreira, 1965; Smith and Vane, 2003). Several SVSPs have also been developed as actual or potential drugs for human use, and these have been discussed in several more recent reviews (Fox and Serrano, 2007; Marsh and Williams, 2005; Phillips et al., 2009; Serrano and Maroun, 2005; Swenson and Markland, 2005); only those with defined thrombin-like properties will be included here.

One of the most promising SV-TLEs for clinical use was Ancrod (Viprinex), a serine proteinase originally isolated from the venom of *Calloselasma* (formerly *Akistrodon*) *rhodostoma* (Au et al., 1993). Its utility in treating stroke victims was evaluated some years ago (Sherman, 2002), and initial indications for acute ischemic stroke were very promising. However, in late 2008, Ancrod failed phase 3 clinical trials for acute ischemic stroke, and it is no longer being developed as a drug for human use in strokes (Neurobiological Technologies, <http://www.ntii.com>). In a recently published study involving 500 patients at several different facilities who received Ancrod within 6 h of symptom onset, Ancrod treatment of acute ischemic stroke victims was halted due to lack of efficacy (Levy et al., 2009). No difference between placebo and Ancrod treatment was seen in positive response of

patients or in ninety day mortality levels, and the incidence of symptomatic intracranial bleeding was approximately twice as great in patients receiving Ancrod. This lack of efficacy was particularly disappointing considering that desired changes in fibrinogen levels (rapid initial defibrinogenation and avoidance of prolonged hypofibrinogenemia) were seen in >90% of Ancrod-treated patients (Levy et al., 2009). Ancrod is still used outside of the United States for several coagulopathies, including deep vein thrombosis and coronary artery bypass surgery (Cole, 1998), but the outlook for more extensive clinical use is poor.

Batroxobin (Itoh et al., 1987) is another TLE (from *Bothrops moojeni* venom) which has been investigated extensively for use in a variety of disorders, including cerebral and myocardial infarction, ischemic stroke, angina and for prevention/treatment of surgical bleeding (Phillips et al., 2009; Xu et al., 2007). A subsidiary of the Chinese biopharmaceutical company Sinobiomed was granted a patent for recombinant batroxobin (rBAT, Defibrase) in 2007, and some recent reports indicate that this TLE may be more successful in clinical trials than Ancrod. In a study of a small group of patients with deep vein thrombosis (DVT), a serious and potential fatal disorder of the lower limbs, batroxobin was found to be effective in abolishing symptoms of DVT (pain, swelling/erythema of lower limbs) and achieving limb salvage (Zhang et al., 2009). Patient monitoring for 1–3 month post-treatment indicated no abnormalities or return of symptoms, and fibrinogen levels were lowered for at least 14 days. An interesting effect of batroxobin treatment was the increase in endothelial progenitor cells in peripheral blood, which were greatly elevated from normal levels (statistically significant) at 7 and 14 days post-administration. Because these cells (CD34+, CD31+, VE-cadherin+ cells) are important in neovessel formation in adults and may be an essential component of vasculogenesis following disease/injury (Allegra et al., 2009; Asahara et al., 1999), batroxobin-stimulated mobilization may be an important component of recovery (Zhang et al., 2009). The mechanism of this action is presently unknown, but the positive results obtained support extending clinical trials to include a larger patient group.

Batroxobin has also been recommended for treatment of patients with ischemic stroke and transient ischemic attack who also show hyperfibrinogenemia (Xu et al., 2007). Intravenous batroxobin was administered in clusters immediately following and at 3 and 6 months after ischemic events; fibrinogen levels decreased significantly after administration at 0 and 3 months, but the decrease was not significant at 6 months. One year survivorship was also significantly greater in the batroxobin-treated group, and incidence of intracranial hemorrhage was not different in the two treatment groups. These indications suggest that batroxobin may be a safer and more effective treatment for ischemia than Ancrod. However, a recent review of the effectiveness of batroxobin to control hemorrhage during thoracic surgery concluded that although some differential effects were observed, no clinically relevant benefit was observed following batroxobin use (Zeng et al., 2009). The authors conclude that there is insufficient evidence supporting any benefit of batroxobin for hemorrhage during thoracic surgery. These conflicting reports suggest that while

batroxobin may have efficacy for controlling some specific types of coagulopathies, it is not generally indicated for all such conditions.

Several additional TLEs are undergoing evaluation in animal models for antithrombotic use. Acutobin, a TLE derived from *Deinagkistrodon acutus* venom, was reported to be effective in reducing mortality and brain damage following ischemia and reperfusion of the cerebral artery in hyperglycemic rats (Wei et al., 2004). This model mimics a condition particularly at risk of brain tissue injury following ischemia, and acutobin treatment resulted in increased brain tissue perfusion and a reduction in the size of infarct. In a very different application of a snake venom TLE, a dental fibrin adhesive was produced from fibrinogen hydrolyzed by TLE from *Crotalus durissus terrificus* venom (Barbosa et al., 2008). Free gingival grafts were immobilized using either TLE or sutures, and at 7 days post-treatment, inflammatory cell density was lower in the TLE treatment group. By 14 and 45 days, no difference was observed between the two treatments. This study demonstrates that TLEs from snake venom can have utility in production of biological products, with medical applications which are only tangentially related to their in vivo direct actions as fibrinogenolytic serine proteases.

Use in Basic Research and Diagnostics

Thrombin-like enzymes have been developed for use as diagnostic reagents for clinical and research labs, and Reptilase®, derived from *B. jararaca* venom, is commonly used in clinical lab diagnosis of bleeding and other coagulation disorders (Phillips et al., 2009; Stocker, 1998). Like several TLEs, Reptilase® shows high specificity for the A α chain of fibrinogen and is not affected by fibrin degradation products (FDPs). Clinically, a thrombin time/Reptilase® time (TT/RT) of >1, which is correlated with the presence of FDPs, is indicative of high potential for disseminated intravascular coagulation, a potentially fatal coagulopathy.

Several other TLEs have been used in a variety of other applications, such as in the production of dental adhesives (Barbosa et al., 2008; see above). Gyroxin, purified from *Crotalus durissus terrificus* venom, was labeled with ^{125}I and used to study biodistribution in a mouse model system (Alves da Silva et al., 2006). The authors suggested that distribution and exogenous compound metabolism could be evaluated with these methods, and it was hypothesized that the distribution kinetics/metabolism patterns observed may be correlated with tissue-specific distribution of different protease activated receptors (PARs) for this (and other) serine proteinases. Ancrod, which may be removed from therapeutic use, has been used as a reagent to study polymerized collagen-fibrin matrices (Rowe and Stegemann, 2009). Collagen-fibrin mixed scaffolds showed strength and tensile stiffness greater than collagen alone, and this mixed matrix may have applications in bioengineering of tissues and biomaterials design generally. Potential further applications were indicated for use in cell culture work, in vitro modeling of vascular flow dynamics and in vivo wound healing (Rowe and Stegemann, 2009). These are but a few examples

of the creative ways in which venom TLEs are being utilized in both applied clinical and basic research.

Future Potential for SV-TLEs

There is a continuing need for safe and effective drugs to treat coagulation disorders such as venous thromboembolic disease and stroke (Spyropoulos, 2008), and research into thrombin-like enzymes from snake venoms could provide novel lead compounds or enzymes which could be directly useful. There is an obvious diversity of SVSPs from front-fanged snakes which could provide a source of novel compounds. However, though variation in component number can exceed 100 protein/peptide compounds in a single venom, there is a relatively small diversity of protein families so far described from venoms (Juárez et al., 2004), and TLEs described thus far appear to possess conserved functional variation along a common theme. This scenario may change as newer methods allow a deeper probe of the venom proteome and reveal diversity of structure (and likely function) among the much less abundant minor venom components (Bandow, 2010; Calvete et al., 2009; Polaskova et al., 2010), but other sources, such as among venoms from rear-fanged snakes, may prove to contain novel TLEs.

Snake venom serine proteases have proven to be useful in various applications in biotechnology and basic research (Wisner et al., 2001), and their specificities could perhaps be exploited for use in mass spectrometry applications currently dominated by trypsin use, such as peptide fingerprinting, MS/MS sequencing, etc. It may be that the most useful applications of SVSPs like the TLEs may lie in research purposes rather than drug development.

Summary and Conclusion

Snake venom thrombin-like enzymes are important components of most viperid snake venoms and are less broadly occurring among other squamate reptile venoms. As part of the biological weaponry of venomous species, their actions *in vivo* can cause cataclysmic coagulopathies which may become life-threatening. Purified and characterized, TLEs have many applications in biomedicine as well as basic and applied research. Rapid advances in genomics and proteomics have provided sequences for many venom serine proteinases, including TLEs, and detailed structure/activity data is available for a smaller subset of these. There is a need for rigorous substrate specificity studies to be conducted with the naturally expressed venom serine proteinases, particularly for those species with extensive transcriptome and proteome datasets. Such functional data will help to answer the remaining questions related to the observed diversity of actions of these structurally conservative venom components. Further, there are many species of front-fanged and rear-fanged snakes whose venoms are poorly known, and it is likely that additional interesting variants of this family of proteinases remain to be described.

Appendix: Identification of Serine Proteinases Used in Sequence Alignments (Fig. 30.1) and Sequence Similarity Analysis (Fig. 30.4), Ordered by UniProt Accession Number

| Accession | Protein names | Organism | Length |
|-----------|---------------------------------------|--|--------|
| P00760 | Trypsin – Bovine cationic | <i>Bos taurus</i> | 246 |
| P07477 | Trypsin-1 (EC 3.4.21.4) | <i>Homo sapiens</i> (Human) | 247 |
| P00766 | Chymotrypsin – bovine | <i>Bos taurus</i> | 245 |
| P00734 | Thrombin – human | <i>Homo sapiens</i> (Human) | 259 |
| A1E235 | Venom thrombin-like enzyme (Fragment) | <i>Deinagkistrodon acutus</i> (Hundred-pace snake) | 235 |
| A1E236 | Venom thrombin-like enzyme (Fragment) | <i>Deinagkistrodon acutus</i> (Hundred-pace snake) | 235 |
| A1E237 | Venom thrombin-like enzyme (Fragment) | <i>Deinagkistrodon acutus</i> (Hundred-pace snake) | 235 |
| A1E238 | Venom thrombin-like enzyme (Fragment) | <i>Deinagkistrodon acutus</i> (Hundred-pace snake) | 217 |
